OVERVIEW\textsuperscript{5,6,7}

Hypertension (HTN) affects over 30 percent of adult Americans and is an independent risk factor for the development of cardiovascular (CV) disease. To reduce the risk of CV events, the current blood pressure goal is less than 140/90 mm Hg for most patients. For patients with diabetes the current blood pressure goal is less than 140/80 mmHg and for patients with chronic renal disease, with or without diabetes, goal for blood pressure therapy is less than 130/80 mm Hg.

Severe HTN (systolic blood pressure $\geq$180 and/or diastolic blood pressure $\geq$120 mg Hg) can produce acute life-threatening complications and considered hypertensive emergencies. Patients with such high HTN who are asymptomatic and do not display acute end organ damage are considered hypertensive urgencies.

Clonidine and guanfacine (centrally-acting alpha2 adrenergic agonists); methyldopa (dihydroxyphenylalanine [DOPA] carboxylase inhibitor; and reserpine (catecholamine reuptake inhibitor) are the focus of this sympatholytic review.

SPECIAL USAGE CONSIDERATIONS\textsuperscript{8}

Abrupt discontinuation of clonidine, regardless of the route of administration, can precipitate a withdrawal syndrome consisting of rebound increases in both serum and urine catecholamines; therefore taper slowly to avoid withdrawal syndrome. Rebound HTN has also been reported with methyldopa and guanfacine.

Methyldopa is contraindicated for use with monoamine oxidase inhibitors (MAOIs), active hepatic disease, such as acute hepatitis and decompensated cirrhosis. Because of the risk of hemolytic anemia, patients receiving methyldopa should have a baseline hemoglobin, hematocrit, or red blood cell count assessed before and during therapy. Positive Coombs' tests occur in ten to 20 percent of patients receiving methyldopa therapy within six to 12 months of therapy, with the lowest incidence occurring with a daily dosage of one gram or less.

Reserpine is contraindicated in patients receiving electroconvulsive therapy (ECT), active peptic ulcer disease or ulcerative colitis, in patients with a history of major depression.

Avoid tricyclic antidepressants (TCAs) with clonidine and reserpine.

Methyldopa oral dosage forms and guanfacine are classified as Pregnancy Category B. Methyldopa/HCTZ, clonidine, and reserpine are Pregnancy Category C. Methyldopa has been used in pregnancy with long-term fetal safety, but it causes sedation.\textsuperscript{9}

Dosage changes may need to be made for each agent based on other concomitant medications decreased renal and/or hepatic function, and tolerability of the agent.
PLACE IN THERAPY

The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC-7), published in 2003, recommends antihypertensives based on compelling indications. Although there are several classes of antihypertensives, the sympatholytics remain a treatment option for hypertension for patients refractory or sensitive to the newer agents.

The oral, centrally-acting, alpha2-adrenergic receptor agonists currently in use include clonidine and guanfacine. Clonidine (Catapres) is available in both a transdermal formulation and an oral formulation for the treatment of hypertension. Clonidine and clorthalidone (Clorpres) are also generically available in a combination tablet formulation. Guanfacine (Tenex) is used alone or in combination with other drugs for the treatment of hypertension. While it is similar to clonidine, guanfacine is more selective for alpha2-adrenergic receptors, longer acting, dosed once daily, and has less frequency and severity of rebound hypertension following abrupt discontinuation. Methyldopa is a centrally-acting antihypertensive agent, which was commonly used in the past for blood pressure control but whose use has largely been replaced by other antihypertensive drug classes with more favorable adverse effect profiles. However, methyldopa is still used in developing countries due to its low cost and in the treatment of chronic hypertension in pregnant women. Hydrochlorothiazide and methyldopa are used together in an oral preparation for the treatment of hypertension. The effects are additive for blood pressure reduction with the combination of hydrochlorothiazide and methyldopa. The combination product may be used once the dose has been successfully titrated and the optimal dose corresponds to a ratio contained in the combination formulation. The use, however, of this combination product should be minimal due to dosing constraints from each individual component found in the combination product. The HCTZ component negates the use of this combination product in pregnant women. Reserpine has been used as a second-line therapy. Recently, the use of reserpine as an antihypertensive agent has diminished due its adverse CNS effects. Newer agents have shown to be much better tolerated.

In the absence of compelling indications, reaching target blood pressure is central in determining cardiovascular benefit in patients with hypertension, not the specific agent used to reach target blood pressure. In hypertensive patients with lower BP goals or with substantially elevated BP, three or more antihypertensive drugs may be necessary.

There are no comparative clinical trials evaluating the sympatholytic antihypertensives. Good quality, double-blind, comparative trials have not been performed with these agents in the management of hypertension.
